Introduction:
Dust aerosols play an important role in the Martian climate system. The spatial and temporal variability and optical properties of atmospheric aerosols have been a target of almost every major spacecraft mission to Mars. Airborne dust is composed mostly of mineral particles lifted from the surface by near-surface winds and presumably by “dust devils”, small-scale convective vortex. Dust participates in heating and cooling of different atmospheric layers absorbing, scattering and reemitting in thermal IR solar radiation [1, 2]. Aerosol particles serve also as cloud condensation nuclei (CCN) in the Martian atmosphere and thus help regulate the transfer of water between the hemispheres [3].

Since condensate clouds were observed in Martian atmosphere, besides the main micron-size mode extended microphysical modeling requires a small dust particle population in the higher region of the atmosphere in order to form a clouds agreeing with data. Some observations supported the bimodal distribution against the mono-modal mostly used to characterize the Martian dust. Based on Viking limb radiances and microphysical modeling, Montmessin et al. (2002) [4] have derived a bimodal distribution at Ls=176° / 15°S (shortly before the dust storm), featuring two maxima with \( r_{\text{eff}}=1.8 \) \( \mu \)m and \( v_{\text{eff}}=0.5 \) \( \mu \)m for the large mode and \(<0.2 \) \( \mu \)m for the small mode, with a ratio of populations (small to large) around 25. Markiewicz et al. (1999) have reported a possible presence of bimodal distribution based on the Imager for Mars Pathfinder (IMP) data on the midday sky brightness in visible-near-IR filters at Ls~156° [5].

Data analysis: The spectral range of SPICAM IR (1-1.7 \( \mu \)m) includes three relatively strong CO₂ absorption bands (1.43, 1.57 and 1.6 \( \mu \)m) and the 1.37-\( \mu \)m H₂O band [6]. To reduce the number of spectral sampling points in solar occultation, the IR spectrum consists of three “windows” and a set of several continuum points [see 6-7 for details]. We used the set of 10 continuum wavelengths outside gaseous absorption bands: 996.4, 1093.7, 1158.2, 1197.0, 1241.4, 1272.9, 1304.4, 1321.9, 1514.6 and 1552.2 nm.

The UV spectrometer measures a spectrum from 118 to 310 nm and includes the absorption bands of CO₂, O₃ and continuum extinction by aerosols. The retrieval method separates the various species in a way described in [8-9]. For the present study, aerosol extinctions at wavelengths of 200, 250 and 300 nm have been used.

belt and the range free of clouds at 60°N.

Figure 2. The IR and UV extinctions for the Southern hemisphere.

The interpretation of the profiles using Mie scattering theory with adequate refractive indices of Martian dust and H$_2$O ice particles allows to retrieve a particle size distribution and number density [7]. Figures 3 and 4 present vertical distributions of particle size for dust, ice and small mode and number density profiles for 5 orbits in the Northern hemisphere for latitudes >60°N, L$_s$=65-85° and for 3 orbits in the Southern hemisphere for latitudes >50S, L$_s$=61-81° as examples.

Summary: For the first time, a combined analysis of the UV and IR channels in the spectral range from 200 to 1550 nm has allowed to derive unambiguously a bimodal size distribution for Martian aerosols in an altitude range of 10-70 km and to track its vertical and temporal evolution:

1) The main mode of the distribution has been determined both for H$_2$O and dust particles with a retrieved average radius of 0.7 and 1.3 μm, respectively. We are unable to separate ice and dust from SPICAM observations, so we based our interpretation on MCS observations for the same season and MY29 [11]

2) A small mode of submicron particles has been detected for both hemispheres. The average radius is 0.044 μm and number density varies from 2 cm$^{-3}$ at 60 km to 10$^5$ cm$^{-3}$ at 20 km for the Northern hemisphere. The average radius is 0.066 μm and the number density ranges from 1 cm$^{-3}$ at 60 km to 10$^3$ cm$^{-3}$ at 20 km for the southern hemisphere. The small mode extends vertically up to 70 km in the Southern hemisphere whereas it remains around 30-40 km in the Northern hemisphere.

Figure 3. Retrieved profiles of particle size and number density for the two modes of the bimodal distribution, assuming dust or ice refraction index. The results for five orbits in the Northern hemisphere for latitudes >60°N are presented.

Figure 4. Same as in Fig. 3 for three orbits in the Southern hemisphere for latitudes >50°S.

3) Low-altitude clouds have been observed at 20-30 km. Such clouds correspond to the poleward edge of the aphelion cloud belt both in the Southern
and the Northern hemisphere. Their opacity in UV and IR is below 0.03.

4) Clouds in the Southern hemisphere have been detected at 40-50 km in the UV only with a total opacity below 0.05, too small to be detected in nadir (sub-visible clouds). The average particle size is \( \mu m \approx 0.06 \) and the number density in the clouds varies from 100 to 5000 cm\(^{-3}\).

5) The highest level of supersaturation at the Northern hemisphere at altitudes of 30-50 km reported in [10] for latitudes > 60°N is consistent with the observed absence of any particles (small or large) above 30 km in our observations. For latitudes below 60°N it is more difficult to explain the supersaturation since at least 10-100 cm\(^{-3}\) particles has been observed at 30-50 km with \( r_{\text{eff}} \approx 0.05 \mu m \) on average. Our estimation of the critical saturation ratio based on the nucleation rate calculation gives \( S_{\text{sat}} \approx 2 \) for particles from 0.01 to 0.1 \( \mu m \). High supersaturation may be explained by several authors [12]. In the Southern hemisphere the small particles with \( r \approx 0.07 \mu m \) are always present but \( S_{\text{sat}} \approx 4 \) derived by Maltagliati et al. (2011) [10] is within the uncertainties of nucleation rate and temperature dependence.

6) Brownian coagulation quickly removes particles with \( r < 0.1 \mu m \) and number density \( \geq 1000 \) cm\(^{-3}\). For the small mode with \( r_{\text{eff}} = 0.04-0.05 \mu m \) and \( N \approx 10^3 \) cm\(^{-3}\) in the Northern hemisphere a source of particles is required to balance the loss by coagulation. Micrometeorite mass flow estimations are too low, whereas a surface source (wind stress dust lifting and dust devils) appears more plausible. In the Southern hemisphere the small mode with \( r_{\text{eff}} \approx 0.07 \mu m \) and \( N \approx 10^3 \) cm\(^{-3}\) is more stable and can survive 50-100 days or more. Similar to the Earth aerosol distribution, coagulation of small particles could explain the bimodal type of distribution.

The Mars Express occultation database is large and is being continuously populated [9, 10]. Further analysis of the IR and UV solar occultations would help to constrain the seasonal and geographical variations of the small and large modes of aerosols. Considering the impact of aerosols on present-day Mars climate, the present study opens a new path of exploration for modelers in their research.
